ABSTRACT

In areas of large lateral variations in velocity, conventional velocity estimation techniques fail and often result in absurd interval velocities because they assume a stratified earth model. The errors in conventional velocity estimation due to lateral velocity variations are shown to be related to the second lateral derivative of the RMS slowness ($1/v_{\text{RMS}}$). This relation is obtained by assuming straight raypaths and approximating the vertical RMS slowness to a given interface as a second order Taylor series expansion in the midpoint direction. Under these approximations, the effect of the first lateral derivative of the slowness on the traveltime is negligible. Knowing the stacking velocity to a given event as a function of midpoint, the lateral derivative method (LDM) can correct for the velocity estimation errors due to lateral velocity variations down to wavelengths on the order of two cable-lengths. Letting Δv be the velocity variation over one cable-length, the LDM is applicable when $\Delta v/v > \sim 2\%$. The assumptions of the method break down, however, when $\Delta v/v > \sim 30\%$.

Linearizing the equation relating the conventional velocity estimates and the true velocity results in a set of equations whose inversion is unstable. However, stability is easily achieved by adding a non-physical fourth derivative term which affects only the higher spatial wavenumbers that are beyond the lateral resolution of the LDM. The velocity estimation procedure, then, is to solve a pentadiagonal system of equations in which the input data are the conventional velocity estimates and the zero-offset traveltimes to a given event.

Synthetic models designed to test the assumptions of the LDM show that none of the assumptions leads to spurious results. Even in the worst possible cases, the LDM results show an improvement over conventional results. A test of the lateral derivative method on field data where there is a lateral velocity variation due to seafloor topography gives a result which is substantiated by a depth migration.

Acknowledgments

This work was funded entirely by the sponsors of the Stanford Exploration Project and I am grateful to them not only for their financial support but also for the advice and suggestions that many of the sponsoring companies' representatives have made during the course of this work.

My advisor, Jon Claerbout, provided the original inspirations for this thesis and was always readily available to discuss the many points of confusion and frustration which came about during the course of this research. Robert Stolt, who also was an interim advisor, provided some valuable insights which made the method described in the thesis considerably more practical. I consider myself extremely fortunate to have had such expert and insightful guidance.

My fellow co-workers Rob Clayton, Heloise Bloxson Lynn, and Ozdogan Yilmaz were more than kind to postpone their own research efforts to help me sort out the mathematical and practical perplexities which at times seemed to be endless or unsolvable. Moreover, Rob Clayton's computer expertise considerably eased my own programming tribulations. Will Gray and Einar Kjartansson kindly provided the ray-tracing and depth-migration algorithms respectively. Rex Hanson set up and ran depth migration. I also benefited greatly from the advice and help of Francis Muir and Fabio Rocca during their "sabbaticals" at Stanford. The development of the double-square-root equation presented herein was actually a group effort of Jon Claerbout and many of my fellow students in the Stanford Exploration Project, and I wish to acknowledge their part in clarifying the mathematical concepts of seismic imaging.

To Heloise I also owe my appreciation for being a patient and loving wife and providing me with the inspiration I needed to finish this work.

Finally, I wish to thank my parents for their continuing support for me during my years of graduate education. It is to the memory of my mother that I dedicate this thesis.
